ABSTRACT

BACKGROUND

The chitinase-like protein YKL-40 is involved in inflammation and tissue remodeling. We recently showed that serum YKL-40 levels were elevated in patients with asthma and were correlated with severity, thickening of the subepithelial basement membrane, and pulmonary function. We hypothesized that single-nucleotide polymorphisms (SNPs) that affect YKL-40 levels also influence asthma status and lung function.

METHODS

We carried out a genomewide association study of serum YKL-40 levels in a founder population of European descent, the Hutterites, and then tested for an association between an implicated SNP and asthma and lung function. One associated variant was genotyped in a birth cohort at high risk for asthma, in which YKL-40 levels were measured from birth through 5 years of age, and in two populations of unrelated case patients of European descent with asthma and controls.

RESULTS

A promoter SNP (−131C→G) in CHI3L1, the chitinase 3–like 1 gene encoding YKL-40, was associated with elevated serum YKL-40 levels (P=1.1×10−13), asthma (P=0.047), bronchial hyperresponsiveness (P=0.002), and measures of pulmonary function (P=0.046 to 0.002) in the Hutterites. The same SNP could be used to predict the presence of asthma in the two case–control populations (combined P=1.2×10−5) and serum YKL-40 levels at birth (in cord-blood specimens) through 5 years of age in the birth cohort (P=8.9×10−3 to 2.5×10−4).

CONCLUSIONS

CHI3L1 is a susceptibility gene for asthma, bronchial hyperresponsiveness, and reduced lung function, and elevated circulating YKL-40 levels are a biomarker for asthma and decline in lung function.
Chitinases are evolutionarily conserved proteins that mediate airway inflammation in mouse models of asthma.\(^1\) The chitinase-like protein YKL-40 lacks chitinase activity but binds ubiquitously expressed chitin and has been implicated in inflammation and tissue remodeling.\(^2\)-\(^6\) We recently demonstrated that serum YKL-40 levels are elevated in patients with asthma and that circulating YKL-40 levels are correlated with asthma severity, thickness of the subepithelial basement membrane, and pulmonary function,\(^7\) suggesting that circulating YKL-40 levels are a biomarker for asthma. The YKL-40 protein is encoded by the chitinase 3–like 1 gene \(CHI3L1\), and single-nucleotide polymorphisms (SNPs) in the \(CHI3L1\) promoter have been associated with elevated serum YKL-40 levels,\(^8\),\(^9\) differential gene expression\(^9\) and transcript levels,\(^10\) and a higher risk of schizophrenia.\(^9\) We conducted a genomewide association study to identify genes that affect serum YKL-40 levels and hypothesized that variation in associated genes influences the risk of asthma and bronchial hyperresponsiveness and is associated with reduced lung function.

**METHODS**

Written informed consent was provided by all adult participants; the children who participated provided oral assent and their parents provided written informed consent. The study was approved by the institutional review boards at the participating centers.

The Hutterites

To minimize the confounding effects of genetic and environmental heterogeneity, we focused our genetic studies of common diseases in the Hutterites.\(^11\),\(^12\) The 753 Hutterites we studied live on communal farms in South Dakota and are related to each other through multiple lines of descent in a 3028-person, 13-generation pedigree with 62 founders.\(^13\),\(^14\) The small number of founding genomes reduces genetic heterogeneity, and the communal lifestyle of the Hutterites ensures that nongenetic factors are remarkably uniform among persons. Smoking is prohibited (and rare) in this community, minimizing exposure to firsthand or secondhand smoke.

Asthma was assessed in 652 Hutterites by obtaining a history of symptoms (cough, wheeze, shortness of breath), bronchial hyperresponsiveness to methacholine inhalation or airway reversibility, and a doctor’s diagnosis, according to previously published protocols.\(^12\),\(^15\) A total of 76 (11.7%) met the criteria for asthma; 80 others (12.3%) had bronchial hyperresponsiveness only, and 423 (64.9%) did not have bronchial hyperresponsiveness and were not symptomatic.\(^12\)

Persons were considered to have atopy if they had a positive skin-prick test for at least 1 of 14 airborne allergens\(^12\); 311 of 702 Hutterites (44.3%) had atopy.

YKL-40 levels were measured in frozen serum specimens from 632 Hutterites who were 6 years of age or older.\(^7\) The clinical characteristics of these 632 Hutterites are shown in Table 1.

*Plus–minus values are means ±SE. Data for serum IgE were available for 610 Hutterites (271 males and 339 females). Data for forced expiratory volume in 1 second (FEV\(_1\)), forced vital capacity (FVC), the FEV\(_1\)/FVC ratio, and the forced expiratory flow between 25% and 75% of the FVC (FEF\(_{25–75}\)) were available for 599 Hutterites (272 males and 327 females).
For genetic studies, we used a natural-log transformation of the serum YKL-40 level to fulfill the distributional requirements of our methods, and we included age and sex as covariates. The heritability of YKL-40 levels was estimated with the use of variance-component methods.\textsuperscript{13,14} We used as a test of association the general two-allele model for quantitative measures (YKL-40 level, pulmonary-function measures, and total serum IgE level).\textsuperscript{16} (For more details of the variance component estimate of heritability, the general two-allele model test of association, and an estimate of the effect size of associated alleles on the trait variance, see the Supplementary Appendix, available with the full text of this article at www.nejm.org.)

Associations with binary phenotypes (asthma, bronchial hyperresponsiveness, and atopy) were assessed using the case–control quasi-likelihood test, which takes into account the relatedness between persons with the phenotypes and controls.\textsuperscript{17}

**The Childhood Origins of Asthma Cohort**

The Childhood Origins of Asthma (COAST) cohort consists of 206 children of European descent (56.8% of whom are boys) who participated in genetic studies in a birth-cohort study of the origins of asthma,\textsuperscript{18} with asthma diagnosed at 6 years of age. Serum levels of YKL-40 were measured in 125 of these children at birth (in cord-blood specimens) and at 1 and 3 years of age and in 105 of these children at 5 years of age.

YKL-40 levels were measured in frozen serum specimens, according to the same protocols used for studies of the Hutterites.\textsuperscript{7} At 6 years of age, the children in the COAST cohort received a diagnosis of asthma if they met at least one of the following criteria: doctor-diagnosed asthma, use of doctor-prescribed albuterol for episodes of coughing or wheezing more than once between 60 and 72 months of age, daily use of controller medication, implementation of a step-up plan as prescribed by a doctor (including the use of albuterol or the short-term use of inhaled corticosteroids during illness), or use of doctor-prescribed prednisone for the treatment of an asthma exacerbation.

The difference in YKL-40 levels between children with asthma and those without asthma were tested using a Wilcoxon rank-sum test. Associations between CHI3L1 SNPs and YKL-40 levels were examined with the use of log-transformed YKL-40 levels at birth and at 1, 3, and 5 years of age in a linear-regression model, with sex included as a covariate.

**Asthma Case Patients and Controls**

Two populations of European descent were used to replicate the associations with asthma. The Freiburg population consists of 344 children with asthma and 294 control children without asthma, recruited from clinics at the Children’s University Hospital in Freiburg, Germany. Asthma was defined by the presence of self-reported symptoms (cough, wheeze, or shortness of breath), current use of asthma medications, a doctor’s diagnosis, and bronchial hyperresponsiveness (i.e., a 15% decrease in the baseline value of the forced expiratory volume in 1 second [FEV\textsubscript{1}] after either inhalation of ≤8 mg per deciliter of histamine or ≤6 minutes of exercise). The controls did not have a history of asthma, recurrent wheezing, or atopy. A total of 64.7% of the case patients were male, with a mean age of 10.1 years (range, 6 to 16) at the time of evaluation; 59.4% of the controls were male, with a mean age of 7.9 years (range, 4 to 16) at the time of enrollment.

The Chicago population consisted of 99 case patients recruited through the adult and pediatric asthma clinics at the University of Chicago Medical Center and 197 controls recruited from the same medical center. Diagnosis of asthma in the case patients was based on fulfillment of all of the following criteria: age of 6 or more years, presence of at least two of three symptoms (cough, wheeze, and shortness of breath), a physician’s diagnosis of asthma (with no conflicting pulmonary diagnosis), either bronchial hyperresponsiveness (defined as a ≥20% decrease in FEV\textsubscript{1} after inhalation of ≤25 mg of methacholine per milliliter) or an increase by 15% or more in FEV\textsubscript{1} after treatment with a short-acting bronchodilator or treatment with inhaled corticosteroids, and less than 3 pack-years of cigarette smoking.\textsuperscript{15} The controls were adults recruited from the University of Chicago Medical Center who did not have a history of asthma (either personally or among first-degree relatives). In all, 32.5% of the case patients were male, with a mean age of 24.4 years (range, 7 to 74) at the time of evaluation; 52.5% of the controls were male, with a mean age of 31.6 years (range, 18 to 69) at the time of evaluation.
Associations with asthma were tested with the use of Fisher’s exact test for differences in the genotypes and allele frequencies between case patients and controls. The 95% confidence intervals were obtained from the hypergeometric distribution of the entries, conditional on fixed margins. The analysis for the two case–control populations combined was done using the Cochran–Mantel–Haenszel method.

**RESULTS**

**CHI3L1, YKL-40, AND ASTHMA PHENOTYPES IN THE HUTTERITES**

Serum YKL-40 levels increased significantly with increasing age in the Hutterites (Pearson’s r=0.21, P<0.001) but did not differ between males and females (t=0.52, P=0.61). Mean YKL-40 levels were increased among Hutterites with asthma (102.7 ng per milliliter) or bronchial hyperresponsiveness (96.5 ng per milliliter), as compared with controls (87.2 ng per milliliter) (P=0.005 and P=0.002, respectively), but as in our previous study the levels did not differ between subjects with atopy (99.4 ng per milliliter) and those without atopy (85.1 ng per milliliter) (P=0.68). Among the Hutterites, serum YKL-40 levels were significantly inversely correlated with FEV₁ (P=0.02) but not with forced vital capacity (FVC) (P=0.16), the FEV₁:FVC ratio (P=0.98), or forced expiratory flow between 25% and 75% of the FVC (FEF25–75) (P=0.41).

To assess the relative contribution of genes to the variance in YKL-40 levels among subjects, we first estimated the heritability of the YKL-40 level. The narrow heritability (h²) of this trait in the Hutterites (±SE) is 0.51±0.10 and the broad heritability (H²) is 1.0±0.16. The high estimate for broad heritability indicates that differences in serum YKL-40 levels among individual Hutterites are due nearly entirely to genetic differences between individual persons. The comparatively large broad heritability indicates the presence of autosomal loci with significant nonadditive (e.g., dominant) effects on YKL-40 levels.

The most significant associations in the genomewide association study were found between the YKL-40 level and SNPs upstream of the gene encoding YKL-40, CHI3L1 (Fig. S1 and S2 in the Supplementary Appendix). The P values for all tested SNPs calculated with the use of the general two-allele model can be obtained from the National Institutes of Health Genotype and Phenotype database, dbGaP (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=gap). To further evaluate the specific contribution of the CHI3L1 locus to the variance in YKL-40 levels, five additional SNPs were genotyped in the Hutterites; the location of these SNPs and the linkage-disequilibrium structure of the gene in this population are shown in Figure 1. Three SNPs on the Affymetrix chip (rs4950929, rs946263, and rs2153101) are in perfect linkage disequilibrium with the functional promoter SNP −131C→G (rs4950929) (r²=1.0) (Fig. 1B, and Fig. S3 in the Supplementary Appendix).

These four SNPs showed the strongest association with serum YKL-40 levels of all the SNPs tested in the Hutterites (P=1.3×10⁻¹² for all four comparisons) (Table 2), and remained statistically significant after correction for the number of SNPs present on the Affymetrix chip (see the Supplementary Appendix). None of the 10 SNPs (Table 2) had significant sex-specific effects on serum
YKL-40 levels. The nonsynonymous SNP in exon 5 (Arg145→Gly) was not significantly associated with YKL-40 levels (P = 0.67) or any other phenotypic characteristic (Table 2). The major (most common) allele at each of the associated SNPs in CHI3L1 is the ancestral allele, according to the sequence of the orthologous gene in the chimpanzee. The −131C→G SNP rs4950928 accounts for 9.4% of the variance in YKL-40 levels in the Hutterites, with the minor G allele having an additive (negative) effect on YKL-40 levels (Fig. 2A).

In the Hutterites, the frequency of the rs4950928 C allele was 0.84 in persons with asthma, 0.83 in persons with bronchial hyperresponsiveness, and 0.79 in controls; the allele was significantly associated with the asthma phenotype (P = 0.047 by the case–control quasi-likelihood test) and the bronchial hyperresponsiveness phenotype (P = 0.002 by the case–control quasi-likelihood test) (Table 2 and Fig. 2B). This SNP was not significantly associated with atopy (P = 0.20 by the case–control quasi-likelihood test) or total serum IgE level (P = 0.37 by the general two-allele model). The rs4950928 C allele was also a significant predic-

tor of decreased FEV₁ (P = 0.046 by the general two-allele model), decreased FEV₁:FVC (P = 0.002 by the general two-allele model), and decreased FEF₂₅–₇₅ (P = 0.03 by the general two-allele model) in the Hutterites (Table 2 and Fig. 2C and 2D).

REPLICATION STUDIES IN THE COAST COHORT
Serum YKL-40 levels were highest at birth and decreased through 3 years of age but were relatively stable between 3 and 5 years of age (Fig. 3, and Table S1 in the Supplementary Appendix). Serum YKL-40 levels at each age were not significant predictors of asthma diagnosis at 6 years of age, although the association at 3 years of age approached statistical significance (P = 0.85 for the 121 subjects at birth, P = 0.82 for the 121 subjects at 1 year of age, P = 0.08 for the 121 subjects at 3 years of age, and P = 0.29 for the 103 subjects at 5 years of age) (all P values by the Wilcoxon test).

We also genotyped the −131C→G SNP (rs4950928) in the children in the COAST cohort. The −131C allele was associated with elevated YKL-40 levels at each age (Fig. 3), indicating that genotype-specific effects on circulating YKL-40 levels are present at birth and remain throughout the first 5 years of life. The changes among ages within genotype groupings were not significant. Among the 178 children whose asthma status was evaluated at 6 years of age, 52 (29.2%) received a diagnosis of asthma. The −131C→G genotype and allele frequencies did not differ significantly between children with asthma and
those without asthma at 6 years of age. This result could be due to the different criteria (based on clinical criteria) used to diagnose asthma in the children in the COAST cohort, the influence of the CHI3L1 SNPs on YKL-40 levels before the onset of asthma-related sequelae, or the SNP having an independent effect on the risk of asthma later in life (i.e., after age 6).

**REPLICATION STUDIES IN THE CASE–CONTROL SAMPLES**

In contrast to the COAST cohort, in the Freiburg population, the prevalence of the −131C allele was significantly greater in the case patients with asthma as compared with controls (frequency of the C allele, 0.81 among the case patients and 0.71 among the controls; \( P = 1.6 \times 10^{-4} \) (Table 3). In particular, the CC genotype was more common in patients with asthma (frequency, 0.66) than in controls (frequency, 0.51); both the CG and GG genotypes were more common among controls (CG frequency, 0.41 vs. 0.29 among the case patients; GG frequency, 0.08 vs. 0.05; \( P = 5.6 \times 10^{-4} \) by Fisher’s exact test, assuming a dominant model). This pattern is similar to that found among the Hutterites. The odds ratio for the presence of one or two −131G alleles (CG or GG, vs. CC) was 0.54 (95% confidence interval [CI], 0.39 to 0.75), indicating that the minor −131G allele is associated with reduced levels of circulating YKL-40 protein confers protection against asthma.

A similar pattern of association was present in the smaller Chicago population, in which the −131G allele was overrepresented in the controls as compared to the case patients (\( P = 0.11 \) by the Fisher’s exact test; \( P = 0.03 \) by Fisher’s exact test, assuming a dominant model; odds ratio for the G allele, 0.56; 95% CI, 0.32 to 0.95) (Table 3). The odds ratio for the G allele (CG or GG, vs. CC) in the two populations combined was 0.54 (95% CI, 0.41 to 0.71) (\( P = 1.2 \times 10^{-5} \) by the Cochran–Mantel–Haenszel method).

**DISCUSSION**

Our study shows that serum YKL-40 level is a highly heritable, quantitative trait in humans and confirms that YKL-40 level is a significant biomarker for asthma susceptibility and reduced lung function. Moreover, genetic variation in CHI3L1 influences serum YKL-40 levels and is associated with the risk of asthma, bronchial hyperresponsiveness, and reduced lung function. Although we cannot statistically distinguish between the implicated SNPs that are in perfect linkage disequilibrium, −131C→G SNP (rs4950928) seems likely to be the causal SNP; it is in the core promoter of CHI3L1, within a binding site for the MYC and MAX transcription factors. The minor allele (−131G on the forward strand) disrupts binding and was reported to be associated with reduced transcription in a luciferase reporter assay, lower messenger RNA levels in peripheral-blood cells, and reduced levels of circulating YKL-40 protein.9 Furthermore, a SNP in strong linkage disequilibrium with −131C→G (rs946263) was found to influence CHI3L1 transcript levels in a genomewide study of gene expression in cells from children with asthma.10 Our results are consistent with these findings and indicate that the −131G allele is protective against asthma and decline in lung function, that this effect is independent of allergic (atopic) pathways, and that the effect of this SNP on circulating levels of YKL-40 is present at birth.

Does the −131C→G SNP, or another SNP in strong linkage disequilibrium with −131C→G, directly influence the risk of asthma and decline in lung function, or are these phenotypic effects mediated through its effect on circulating levels of YKL-40? Our study and previous studies show-
ing an association between serum YKL-40 levels and a number of inflammatory conditions,\textsuperscript{2,8} including asthma,\textsuperscript{7} or between SNPs in \textit{CHI3L1} and serum YKL-40 levels\textsuperscript{8,9} and gene expression,\textsuperscript{9,10} suggest that YKL-40 is an intermediate phenotype for asthma susceptibility. However, our results in the Hutterites and the COAST cohort do not allow us to reach this conclusion. For example, in the Hutterites, YKL-40 levels are not associated with the lung-function measures of \textit{FEV}_{1}:/FVC and \textit{FEF}_{25–75}, yet the −131C→G SNP is a significant predictor of both (Table 2). In the COAST cohort, the −131C→G SNP is associated with YKL-40 levels at birth through 5 years of age but not with asthma at 6 years of age (Fig. 3). Thus, the possibility remains that variation in \textit{CHI3L1} exerts effects on the risk of asthma and on lung function that are independent of circulating levels of YKL-40. Formal proof will require studying a larger population, with determinations of both serum YKL-40 levels and asthma status.

In summary, we identified an asthma susceptibility locus, \textit{CHI3L1}, and showed that studying the genetics of quantitative traits (serum biomarkers) associated with asthma can identify asthma susceptibility loci. In the Hutterites, the \textit{CHI3L1} locus explains 9.4% of the variance in serum YKL-40 levels, suggesting that additional loci influence YKL-40 levels. Identifying the remaining loci that contribute to differences in serum YKL-40 levels and related proteins could identify additional genes with a significant effect on the risk of asthma and on lung function.

Supported by grants from the National Heart, Lung, and Blood Institute (HL85197, HL72414, HL56399, HL66533, and HL49596, to Dr. Ober; HL61879 and HL70831, to Dr. Lemanske; HL81638 and HL56389, to Dr. Elias; and M01 RR00055, to the University of Chicago Clinical Research Center).

Dr. Elias reports receiving grant support from MedImmune, a company exploring the regulation of YKL-40 as a therapy for asthma, and consulting fees from Eli Lilly, Pfizer, Promedior, MedImmune, Roche, and Millennium. A U.S. patent (no. 7,214,373) entitled “Methods, compositions and kits relating to chitinases and chitinase-like molecules and inflammatory disease” was issued on May 8, 2007, and is exclusively licensed to MedImmune (now owned by AstraZeneca); Dr. Elias is one of the inventors.

Dr. Chupp reports receiving speakers' fees from GlaxoSmithKline, Merck, AstraZeneca, and Novartis and grant support from Wyeth, Centocor, Pfizer, and Novartis. No other potential conflict of interest relevant to this article was reported.

We thank the Hutterites and the subjects in Chicago, Freiburg, and Madison for their participation in these studies and Kathy Roberg, Christopher Tisler, and Rebecca Anderson for technical support.
